Physical activity and self-reported health status among adolescents: a cross-sectional population-based study

I Galán, R Boix, M J Medrano, P Ramos, F Rivera, R Pastor-Barriuso, C Moreno

ABSTRACT

Objectives: Little is known about the dose–response relationship between physical activity and health benefits among young people. Our objective was to analyse the association between the frequency of undertaking moderate-to-vigorous physical activity (MVPA) and the self-reported health status of the adolescent population.

Design: Cross-sectional study.

Setting: All regions of Spain.

Participants: Students aged 11–18 years participating in the Spanish Health Behaviour in School-aged Children survey 2006. A total of 375 schools and 21 188 students were selected.

Main outcomes: The frequency of undertaking MVPA was measured by a questionnaire, with the following four health indicators: self-rated health, health complaints, satisfaction with life and health-related quality of life. Linear and logistic regression models were used to analyse the association, adjusting for potential confounding variables and the modelling of the dose–response relationship.

Results: As the frequency of MVPA increased, the association with health benefits was stronger. A linear trend (p<0.05) was found for self-rated health and health complaints in males and females; for health-related quality of life this relationship was quadratic for both sexes (p<0.05). For self-reported health and health complaints, the effect was found to be of greater magnitude in males than in females and, in all scales, the benefits were observed from the lowest frequencies of MVPA, especially in males.

Conclusions: A protective effect of MVPA was found in both sexes for the four health indicators studied, and this activity had a gradient effect. Among males, health benefits were detected from very low levels of physical activity and the magnitude of the relationship was greater than that for females.

INTRODUCTION

According to the WHO,1 physical inactivity is the fourth most important risk factor affecting global mortality, to which nearly 6% of all deaths are attributed. In the adolescent population, short-term benefits related to physical activity (PA) are the improvements in lipid profile, blood pressure, metabolic syndrome, muscular strength and bone density, together with a reduction in obesity...
Physical activity and health status among adolescents

and overweight levels, as well as a decrease in emotional problems and depressive symptoms. Moreover, young people who undertake PA adopt healthy behaviour more easily and have better levels of academic achievement and cognitive functioning.

The dose–response relationship between PA and various health indicators has mainly been studied in the adult population, where there is still a controversy about whether or not this relationship is linear. Ekelund et al. in a pooled data analysis of 14 studies in children and adolescents found a direct benefit between three tertiles of moderate-to-vigorous physical activity (MVPA) in relation to cardiometabolic outcomes. Although the WHO recommends that all children of 5–17 years of age take at least 60 min of daily MVPA, little is known about the nature of the relationship in this population. Therefore, finding out the effect on health of several levels of PA could have important implications for improving the recommendations regarding this activity.

It should be emphasised that the concepts underlying the health status in children and adolescents differ from those for adults. As young people are still developing, the measurement of health status must be approached from a global and comprehensive perspective for each individual. Concepts such as ‘subjective health’ and ‘health-related quality of life’ cover complex physical, emotional, mental and social aspects. Hence, it is important to evaluate if the effect of the PA is distributed in a distinct way for the different dimensions of health status.

Finally, although PA varies considerably depending on age and sex, to our knowledge, there have been very few studies in the literature about the role that these variables play regarding the effect of PA on health.

The objective of this study was to analyse the association between the frequency of undertaking MVPA and the different dimensions of adolescent health status, assessing if this relationship differs according to age and sex.

METHODS

Study population

The source of information was the Health Behaviour in School-aged Children (HBSC) study carried out in 2006. The population was a representative sample of preadolescents and adolescents, with an age range of 11–18 years, resident in Spain and enrolled in school from the fifth year of primary school to the last year of upper secondary school (2nd year of baccalaureate). A multistage stratified random sampling was used, taking into account the age strata (4 groups), region (17 autonomous communities), school site (rural and urban) and type of school (public and private). Initially, 480 schools were contacted of which 377 (103 private and 274 public schools) agreed to participate in the study, which represented a response rate of 78.5%. On average, three classes were selected in each school.

A total of 22,350 questionnaires were collected, although subsequently 539 were excluded because of non-response to questions about sex and age, or lack of response to more than 50% of the questionnaire. The sample size was 21,811 participants. The study was carried out in spring 2006. Previously trained survey technicians visited the selected schools, where the students completed an anonymous questionnaire during normal school hours.

This study was approved by the Institutional Review Board of the Carlos III Institute of Health.

Study variables

Health status was measured using four indicators: (1) self-rated health was measured using the question “Would you say that your health is: excellent, good, fair or bad?” Optimal health status was categorised by a response of excellent or good, and suboptimal health status was categorised by a response of fair or bad. (2) The health complaints indicator was assessed using a scale based on the HBSC-Symptom Checklist, which is a list of eight physical and psychological symptoms (headaches, abdominal pain, backache, feeling low, irritability, nervousness, sleeping difficulties and dizziness) to estimate their frequency during the last 6 months. Having two or more symptoms with a frequency of several times a week or daily was considered to define having noticeable subjective health complaints. (3) Satisfaction with life was estimated using the Cantril Ladder, in which, the participant was asked “on which rung of the ladder (scale from 0 to 10) do you feel you stand at this moment in your life?”, with 0 being the worst score and 10 the best. A score of 0–5 was categorised as dissatisfied, whereas a score of 6–10 was categorised as satisfied. (4) Health-related quality of life was measured using the Kidscreen-10 index, a series of 10 questions about mood, ability to concentrate, energy, vitality, well-being and ability to have fun with friends. Each question has five categories of response ranging from ‘never’ to ‘always’ or from ‘not at all’ to ‘extremely often’. The items fulfil the assumptions of the Rasch model. To make the interpretation more applicable, the scores of the Rasch scales are translated into T-values with scale means of 50 and SD of 10, with higher values indicating higher health-related quality of life.

The frequency of MVPA was measured using the question: “in the last seven days, considering moderate and vigorous activity … On how many days did you feel you were physically active for a total of 60 minutes per day?” The response categories were from 0 to 7 days.

The following factors were considered as potentially confounding variables for the association between health status and frequency of MVPA: (1) personal variables (sex, age, country of birth, current smoker, alcohol consumption, and body mass index (BMI)) calculated as
the ratio of weight in kg/height in m² from self-reported
weight and height and defining overweight and obesity
using the cut-off points proposed by Cole et al.,26 con-
sumption of fruit and vegetables, daily breakfast,
number of hours spent each day watching television and
using computers or game consoles, number of hours
spent each day doing school homework); (2) family vari-
ables (employment status of the father, employment
status of the mother, family purchasing power—
measured by the Family Affluence Scale;27 an index
estimated by four items: number of times that the ado-
lescents have been on holiday with their family in the
last 12 months; does the family own a car or van; does
the student have his/her own bedroom; number of
computers owned by the family; country of birth of
the father, country of birth of the mother and type of
household; both parents, single parent or blended
family; and number of minors in the household and
number of adults in the household); and (3) relation-
ships with the school, the family and friends (academic
achievement, satisfaction with family relationships and
satisfaction with relationships with friends). The vari-
ables are categorised in table 1.

Data analysis
The questionnaires with missing values were excluded
from data analysis, so that the number of subjects
studied was 17 467 for self-rated health; 17 358 for satis-
faction with life; 16 803 for health complaints; and
16 560 for health-related quality of life. The sample
excluding the missing values was similar to the original
(there was no statistically significant difference).

Continued
comparing the main socioeconomic variables, health status and the frequency of undertaking MVPA.

The complex sampling design was taken into account during analysis by using the ‘Survey Data’ module of the statistical package Stata V.11. SEs were computed by using the linearised variance estimator based on a first-order Taylor series. Prevalence was calculated for optimal self-rated health, low level of health complaints, high satisfaction with life and the means for the scores on the scale for health-related quality of life, with 95% CIs, both global and for the categories of each one of the exposure variables.

Regression models were used, logistic ones for the estimation of the OR of prevalence and linear ones for the calculation of the regression coefficients, adjusting for the potential confounding variables aforementioned. All covariables were added simultaneously into the models. First, we calculated the association between the frequency of undertaking MVPA and health status by estimating OR for the following categories: 1–2, 3–4, 5–6 and 7 days, using ‘never’ as the reference. Second, linear and quadratic trends of the association between MVPA and the health indicators were calculated from the regression models. For the linear trend, the average value for each category was used, modelling it as a continuous variable, while for the quadratic trend the squares of these values were used. Statistical significance was set at p<0.05.

To further explore the relationships between MVPA and health-status indicators without imposing any particular functional form for the dose–response trends, the amount of MVPA was entered in regression models using restricted quadratic splines with knots at 1, 3.5 and 6 days/week.28 Restricted quadratic splines allow for different quadratic trends within each intermediate category and linear trends in boundary categories, and hence they can accommodate a wide variety of smooth dose–response curves, while avoiding implausible shapes at the tails of the exposure distribution.

Interactions between MVPA, age and sex were evaluated. Given that interactions were found in the relationship between the frequency of MVPA and health status according to sex, the results are shown separately for males and females.

RESULTS

Table 1 describes the health status of the questionnaire respondents, as estimated by the four health indicators. A total of 91.1% (CI 95% 90.3% to 92.0%) declared that they had an optimal self-rated health, 67.4% (CI 95% 66.1% to 68.5%) had a low level of health complaints and 90.9% (CI 95% 90.1% to 91.6%) reported a high satisfaction with life. The mean score on the scale for health-related quality of life was 47.1 (CI 95% 46.5 to 47.6).

According to all the indicators used, the level of health was better, in a statistically significant way, for the questionnaire respondents who indicated that they undertook MVPA more frequently, with gradual increases depending on the categories of MVPA.
(table 1). The rest of the potentially confounding variables considered were also associated with self-rated health, less health complaints, high satisfaction with life and health-related quality of life (tables 1 and 2).

No statistically significant interactions were found between MVPA and age, whereas statistical significance was reached between MVPA and sex for the indicators self-rated health and satisfaction with life. Tables 3 and 4 and figure 1 show the results of the multivariate analysis that evaluated, for each sex separately, the association of the frequency of undertaking MVPA with the different indicators of health status, controlling the effect on this association of personal and family factors. For both boys and girls, there was a positive, graded and statistically significant association (linear trend, \( p<0.001 \)) between MVPA and self-rated health (table 3), with ORs that ranged in males from 2.37, for those who undertook MVPA on 1–2 days, to 4.60 and 4.05, for those undertaking it on 5–6 and 7 days, respectively. Moving from less than 5 days to 5–6 days of MVPA, the OR increased from 2.54 to 4.60. In females, although a positive association was also found, the magnitude of the benefits on self-reported health was lower, with values that were half those for the males (OR=2.14, if MVPA undertaken 7 days).

Regarding less health complaints (table 3), an increase in the positive effects was seen in males from small...
amounts of MVPA on 1–2 days (OR=1.66, p=0.008), which increased further to an OR of nearly 2 for MVPA on 5–6 days. In females, this effect was lower, reaching statistical significance after MVPA on 5–6 days with an OR of 1.46 (p=0.009). The linear trend p value was statistically significant (p<0.001) in both males and females.

The degree of satisfaction with life (table 3) was also shown to be significantly associated with the frequency of undertaking MVPA; among the boys, the OR for high satisfaction increased to 1.99 if PA was undertaken on 1–2 days/week, and satisfaction remained at these values for frequencies of more than 5 days of MVPA.
In girls, the magnitude of the effect was similar, but the gradient was steeper. The linear trend p value was statistically significant for females (p<0.001), but not for males.

Table 4 shows the same analysis applied to health-related quality of life, considering it as a continuous variable and using linear regression to analyse it. In males, an increasing dose–response effect was seen,
especially noticeable after 5 days/week of MVPA ($\beta=3.03$), which increased even further, to 5.08, for those undertaking MVPA for 7 days/week. In females, the benefits were lower at low levels of frequency of MVPA, but reached the same magnitude from 5 days of MVPA. Overall, this indicator was the one that showed fewer differences between boys and girls, as can be seen in figure 1. The quadratic trend p value was statistically significant in males (p=0.006) and females (p<0.001).

**DISCUSSION**

**Principal findings**

The results of this study clearly show that the benefits of undertaking PA on the health status of adolescents enrolled in schools in Spain. The following results should be highlighted: (1) the magnitude of the effect, with benefits for optimal health reaching OR higher than 4 for males who undertook MVPA daily or on most days, as compared with those who never undertook it; (2) the existence of a dose–response effect, with the positive effects increasing in accordance with the increase in the frequency of MVPA; (3) the consistency of the results with the association present for the four health indicators in both sexes; and (4) the greater positive effect in males, especially at low levels of frequency of MVPA.

Few studies have linked the effect of MPV A on general indicators of health status in adolescents. Using data from the HBSC study for adolescents from North America, Western Europe, Eastern Europe, Northern Europe and Southern Europe, Iannotti et al. evaluated the relationship between the frequency of PA and self-rated health, health complaints and satisfaction with life and found, as in our study, beneficial effects for all three indicators.

**Dose–response relationship**

The dose–response relationship between PA and health implies that increases in PA are related with additional improvements in health status, even when it is not undertaken very frequently. This has also been found in other studies regarding dyslipidaemia, blood pressure, overweight and obesity, metabolic syndrome and mental health. However, to our knowledge, there are no comparable studies that measure the nature of the relationship on general indicators of health status. Indeed, there is a controversy about whether this relationship is linear or curvilinear, as some studies have found linear patterns, whereas others have not, probably because the patterns can be different depending on the health effect that is being assessed. In our study, a curvilinear relationship was found with a slight slowdown in the health benefits beyond 3–4 days of MVPA in the following indicators: self-rated health; health complaints; and satisfaction with life. In contrast, for health-related quality of life in both sexes, the benefits increased from these intermediate levels of MVPA. These differences in the dose–response relationship suggest that the effect varies depending on the different dimensions of health status to which the indicators are related. Although self-rated health has been proposed as a measurement of the summary effect of multiple dimensions of health, it is more closely related to the physical dimension rather than the mental and social ones. Similarly, the scale for health complaints is related to symptoms with psychosomatic components very frequently associated with adolescence. Yet, the scale for the quality of life, besides including such physical and mental dimensions, also incorporates family and social relationships, which could suggest that these additional dimensions may be involved in the achieving of greater health benefits with the maximum frequencies of MVPA.

It should be stressed that the benefits to health status are obtained from low levels of MVPA, especially for boys. Similar results have been reported for self-rated health in a young adult population and regarding blood pressure and dyslipidaemia in adolescents. This may have important implications for the preventive recommendations because (although 60 min of PA is currently recommended, if possible on a daily basis) the fact that positive results of a moderate magnitude can be achieved with very small amounts of MVPA may encourage the participation of the more sedentary people. Nevertheless, the maximum benefits were obtained according to public-health recommendations, so the message should be ‘even a little is good; more is better’.

**Gender differences**

The results in health that are derived from undertaking MVPA are greater in males, especially in self-rated health and, to a lesser extent, in having less health complaints. According to our study, females need to undertake more days of MVPA to obtain similar health benefits. However, the effect on satisfaction with life and health-related quality of life was fairly similar in males and females. These differences suggest that the variation of the effect of MVPA according to sex could also be associated to different dimensions of health status. Previous reviews have clearly shown important differences between males and females in the quantity, intensity and type of PA, and that, in part, these distinctions could be explained by biological differences and those relating to sociocultural environment and body image. It would, therefore, be interesting for subsequent studies to undertake detailed research about this relationship.

**Strengths and weaknesses**

To aid correct interpretation of these data, several limitations should be mentioned. First, the limitation in causal inference, stemming from the cross-sectional nature of the study, would theoretically affect the temporality of the association. That is, people who have health problems can have limitations in undertaking physical exercise. However, from the data of the National Health Survey of 2006, only 1.7% of adolescents between 16...
and 19 years do not undertake the leisure time physical exercise that they would like to take because of health problems; hence, this figure would not affect the results obtained. Second, the measurement of health status, MVPA and several covariables of the study is based on self-reported information. Although it is difficult to anticipate the magnitude and direction of the bias induced by measurement error in self-reported PA without validity or reproducibility substudies, some degree of attenuation in the underlying trends would be expected if the misclassification of PA status was non-differential with respect to health outcomes. Nevertheless, the measurement of health status using subjective health scales, as in this present study, has been validated in previous studies, and such scales are considered to be useful tools especially in the stage of adolescence, when psychological aspects are so important in the feeling of well-being among young people. The variable used for estimating MVPA has been previously validated in an adolescent population of Spain, obtaining an acceptable level of validity when compared with measurement using accelerometers. Other variables, such as self-reported BMI or tobacco consumption, have also been validated in Spain, by comparing them with objective measurements.

Third, it has not been possible to differentiate the effect of the intensity of PA, which is a dimension independently related with self-rated health.

The main strengths of this study are the representativeness and large size of the sample used, which means that the results can be extrapolated accurately, and that the methodology employed is the standard one for the HBSC study. This is a collaborative WHO study in which more that 40 Western countries (including Spain) have participated.

CONCLUSIONS
To sum up, an association was found between the frequency of undertaking self-reported MVPA and the health status of adolescents enrolled in schools in Spain. A linear trend was found for self-rated health, health complaints and for satisfaction with life. For health-related quality of life the relationship was quadratic. The benefits of MVPA on health were detected from very low levels, below those established by current recommendations. In general, the magnitude of association was lower in females than in males, a finding that needs to be explained by subsequent research.
